

In traditional mathematics, we distinguish a few different number sets. The basis for all of them is the set of numbers we use for ‘counting’ things – these numbers are called _____. Operations on these numbers include _____, _____ and _____ with the next operation being basically just a convenient way to express repetition of the previous one.

Next in line is the set of _____ – numbers which can be positive or negative and thus moreover express notions like ‘absence’ or ‘debt’. Often defined as _____ between two positive numbers, they also include the operation of _____ which isn’t sensible on positive numbers as the _____ of two positive numbers may be negative.

If we also in need of numbers able to express *parts of objects*, _____ numbers come to the rescue. We write them as either decimal numbers or _____, with the latter form getting across the idea that they are essentially results of dividing one whole number by another: or, as we call the results of division, _____.

Finally, there are also irrational numbers – numbers which literally can’t be written as a ‘ratio’ of two whole numbers. They come about for example as _____ of many positive numbers that are not powers of other numbers, like 2, 3 or 5. The numbers that also include irrational numbers and are heavily used in geometry are called _____.
